Abstract—This paper proposes ChordReduce, a novel implementation of Chord that acts as middleware for creating and running MapReduce jobs. ChordReduce satisfies the desired properties for a distributed MapReduce platform. Chord is a peer-to-peer networking protocol for distributed storage and file sharing that provides $\log_2(n)$ lookup time for any particular file or node. Files and nodes are evenly distributed across a ring overlay and organized such that the responsibilities of a failed node are automatically reassigned. ChordReduce leverages these features to distribute Map and Reduce tasks evenly among nodes and maintain a high degree of robustness during execution. The loss of a single node or a group of nodes during execution does not impact the soundness of the results and their tasks are automatically reassigned. An additional benefit is that nodes joining the ring during runtime can automatically have work distributed to them.

MapReduce frameworks are generally hierarchical, with the responsibility of scheduling work, distributing data and tasks, and tracking progress at the top. This leads to centralized MapReduce implementations having a single point of failure. A MapReduce framework with both responsibility and work distributed among its members would eliminate the need for a central source of coordination. Such a framework would need to be highly scalable, fault-tolerant during execution, able to handle a high degree of churn, and minimize the amount of traffic that results from maintaining the network.

Our experiments show that ChordReduce is an efficient implementation of MapReduce. The applications are far-reaching, especially for big data problems and those that are massively parallel. Implementing MapReduce on a Chord peer-to-peer network demonstrates that the Chord network is an excellent platform for distributed and concurrent programming in cloud and loosely coupled environments.

I. INTRODUCTION

Google’s MapReduce [1] paradigm has rapidly become an integral part in the world of data processing and is capable of efficiently executing numerous Big Data programming and data-reduction tasks. By using MapReduce, a user can take a large problem, split it into small, equivalent tasks and send those tasks to other processors for computation. The results are sent back to the user and combined into one answer. Many popular platforms for MapReduce, such as Hadoop [2], utilize a central source of coordination and organization to store and operate on data. The hierarchical structure of Hadoop results in a single point of failure at the node that concentrates the results and also requires a complicated scheme for handling node failures.

We have developed a system, called ChordReduce, which employs a less hierarchical structure. It is a system that can scale, is fault tolerant, has a minimal amount of latency, and distributes tasks evenly. ChordReduce leverages the underlying protocol from Chord [3] to distribute Map and Reduce tasks to nodes evenly, provide greater data redundancy, and guarantee a greater amount of fault tolerance. Rather than viewing Chord solely as a means for sharing files, we see it as a means for distributing work. This paper establishes the effectiveness of using Chord as a framework for distributed programming. At the same time we avoid the architectural and file system constraints of systems like Hadoop.

Chord [3] is a peer-to-peer (P2P) protocol for file sharing and distributed storage that guarantees a high probability $\log_2 n$ lookup time for a particular node or file in the network. It is highly fault-tolerant to node failures and churn, the constant joining and leaving of nodes. It scales extremely well and the network requires little maintenance to handle individual nodes. Files in the network are distributed evenly among its members.

Our experiments demonstrate that the ChordReduce framework is highly scalable, solving problems significantly faster when distributed. The larger the problem is, the greater the speedup gained by incorporating more nodes into the problem. Our framework also provides a high level of robustness during execution; we can lose many nodes to churn, and still process jobs successfully. If we find a job requires more computational power, we can add more nodes to the job during runtime.

While Chord could be used to implement a grid computing environment similar to BOINC [4] or Folding@home [5], it would be difficult to efficiently implement the MapReduce algorithm using grid computing tools. MapReduce uses persistent data to amortize the cost of distributing the data across the nodes over many calls, while grid environments typically transmit a transient bundle of data and computation to a volunteer node. BOINC and Folding@home use a master-slave architecture with a critical point of failure similar to Hadoop, while ChordReduce is a true peer-based approach.

Section II covers the background of the Chord and MapReduce. Related Work is discussed in Section III. Details of ChordReduce’s implementation and code is described in Section IV, while our experiments and their results are covered in Section V. Lastly, Section VI discusses potential avenues for future research.

Fig. 1: A Chord ring with 16 nodes. The bold lines are incoming edges. Each node has a connection to its successor, as well as 4 fingers, some of which are duplicates.

II. BACKGROUND

Chord and MapReduce are integral parts of ChordReduce. We summarize these frameworks in this section.

A. Chord

Chord [3] is a P2P protocol for file sharing that uses a hash function to assign addresses to nodes and files for a ring overlay. The Chord protocol takes in some key and returns the identity (ID) of the node responsible for that key. These keys are generated by hashing a value of the node, such as the IP address and port, or by hashing the filename of a file. The hashing process creates a m -bit hash identifier.

The nodes are then arranged in a ring from the lowest hash-value to highest. Chord takes the files and places each in the node that has the same hashed identifier as it. If no such node exists, the node with the first identifier that follows this value is selected. Since the overlay is a circle, this assignment is computed in modulo 2^m space.

The node responsible for the key κ is called the *successor* of κ , or $successor(\kappa)$. For example, if there were some portion of the network with nodes 20, 25, and 27, node 25 would be responsible for the files with the keys (21,22,23,24,25). If node 25 were to decide to leave the network, its absence would be detected by node 27, who would then be responsible for all the keys node 25 was covering, in addition to its own keys.

With this scheme, we can reliably find the node responsible for some key by asking the next node in the circle for the information, who would then pass the request through the circle until the successor was found. We can then proceed to directly connect with the successor to retrieve the file. This naive approach is largely inefficient, and is a simplification

Fig. 2: Alice has incorrectly determined that Carol is her appropriate successor. When Alice stabilizes, Carol will let her know about Bob.

Fig. 3: After completing stabilize, Alice makes Bob her successor and notifies him. Bob then made Alice as his predecessor.

of the lookup process, but it is the basis of how Chord theoretically works.

To speed up the lookup time, each node builds and maintains a *finger table*. The *finger table* contains the locations of up to m other nodes in the ring. The i th entry of node n 's *finger table* corresponds to the node that is the $successor(n + 2^{i-1}) \bmod 2^m$. Hash values are not perfectly distributed, it is possible to have duplicate entries in the *finger table*. An example Chord network with fingers is shown in in Fig. 1.

When a node n is told to find some key, n looks to see if the key is between n and $successor(n)$ and return $successor(n)$'s information to the requester. If not, it looks for the entry in the finger table for the closest preceding node n' it knows and asks n' to find the successor. This allows each step to skip up to half the nodes in the network, giving a $\log_2(n)$ lookup time. Because nodes can constantly join and leave the network, each entry in the table is periodically checked and updated during a finger maintenance period.

To join the network, node n first asks n' to find $successor(n)$ for it. Node n uses the information to set his successor, but the other nodes in the ring will not acknowledge n 's presence yet. Node n relies on the stabilize routine to fully integrate into the ring.

The stabilize routine helps the network integrate new nodes and route around nodes who have left the network. Each node periodically checks to see who their successor's predecessor is. In the case of a static network, this would be the checking node. However, if the checking node gets back a different node, it looks at that returned node's hash value and changes its own successor if needed. Regardless of whether the checking

node changes its successor, that node then notifies the (possibly) new successor, who then checks if he needs to change his predecessor based on this new information. While complex, the stabilization process is no more expensive than a heartbeat function. A more concrete example:

Suppose Alice, Bob, Carol, and Dan are members of the ring and everyone happens to be ordered alphabetically (Fig. 2). Alice is quite sure that Carol is her successor. Alice asks Carol who her predecessor is and Carol says Bob is. Since Bob is closer than Carol, Alice changes her successor to Bob and notifies him.

When Bob sees that notification, he can see Alice is closer than whoever his previous predecessor is and sets Alice to be his predecessor. During the next stabilization cycle, Alice will see that she is still Bob's predecessor and notify him that she's still there (Fig. 3).

To prevent loss of data due to churn, each node sends a backup of their data to their successor. Section IV discusses the implementation of the backup process in ChordReduce and expands upon it for backing up Map and Reduce tasks.

B. MapReduce and Hadoop

At its core, MapReduce [1] is a system for division of labor, providing a layer of separation between the programmer and the more complicated parts of concurrent processing. The programmer sends a large task to a master node, who then divides that task among slave nodes (which may further divide the task). This task has two distinct parts: Map and Reduce. Map performs some operation on a set of data and then produces a result for each Map operation. The resulting data can then be reduced, combining these sets of results into a single set, which is further combined with other sets. This process continues until one set of data remains.

The classic example given for MapReduce is counting the occurrence of each word in a collection of documents. The master node splits up the documents into multiple blocks and sends them off to workers. Each worker then goes through their blocks and creates a small word frequency list. These lists are then used by other workers, who combine them into larger and larger lists, until the master node is left with a word frequency list of all the words in the documents.

One very popular open-source implementation of MapReduce is Apache's Hadoop [2]. Hadoop serves as both a distributed file system and framework for MapReduce [6]. However, Hadoop's MapReduce framework is very strongly tied to the Hadoop Distributed File System (HDFS) and the hierarchy of servers that is used by it. Hadoop is centralized around the NameNode. The NameNode's job is to organize and distribute information to the slave nodes, called DataNodes. This makes the NameNode a single point of failure [6] in the network, as well as a potential bottleneck for the system [7].

To do work on Hadoop, the user stores their data on the network. This is handled by the NameNode, which equally apportions the data among the DataNodes. When a user wants to run some analysis on the data or some subset the data,

then that function is sent by the NameNode to each of the DataNodes that is responsible for the indicated data. After the DataNode finishes processing, the result is handled by other nodes called Reducers which collect and reduce the results of multiple DataNodes.

III. RELATED WORK

We have identified two papers that focus on combining P2P concepts with MapReduce. Both papers are similar to our research, but differ in crucial ways.

A. P2P-MapReduce

Marozzo et al. [8] investigated the issue of fault tolerance in centralized MapReduce architectures such as Hadoop. They focused on creating a new P2P based MapReduce architecture built on JXTA [9] called P2P-MapReduce. P2P-MapReduce is designed to be more robust at handling node and job failures during execution.

Rather than use a single master node, P2P-MapReduce employs multiple master nodes, each responsible for some job. If one of those master nodes fails, another will be ready as a backup to take its place and manage the slave nodes assigned to that job. This avoids the single point of failure that Hadoop is vulnerable to. Failures of the slave nodes are handled by the master node responsible for it.

Experimental results were gathered via simulation and compared P2P-MapReduce to a centralized framework. Their results showed that while P2P-MapReduce generated an order of magnitude more messages than a centralized approach, the difference rapidly began to shrink at higher rates of churn. When looking at actual amounts of data being passed around the network, the bandwidth required by the centralized approach greatly increased as a function of churn, while the distributed approach again remained relatively static in terms of increased bandwidth usage.

They concluded that P2P-MapReduce would, in general, use more network resources than a centralized approach. However, this was an acceptable cost as the P2P-MapReduce would lose less time from node and job failures [8].

While P2P-MapReduce is decentralized, it still relies on a very definite master/slave hierarchy for organization, computations, and scaling. During simulation, 1% of the entire network was assigned as master nodes. This means for a simulation of 40000 nodes, 400 were required to organize and coordinate jobs, rendering them unable to do any processing. In addition, a loosely-consistent distributed hash table (DHT) such as JXTA can be much slower and fails to maintain the same level of guarantees as an actual DHT, such as Chord [10].

B. MapReduce using Symphony

Lee et al.'s work [11] draws attention to the fact that a P2P network can be much more than a way to distribute files and demonstrates how to accomplish different tasks using Map and Reduce functions over a P2P network. Rather than using Chord, Lee et al. used Symphony [12], another DHT

protocol with a ring topology. To run a MapReduce job over the Symphony ring, a node is selected by the user to effectively act as the master. This ad-hoc master then performs a bounded broadcast over a subsection the ring. Each node repeats this broadcast over a subsection of that subsection, resulting in a tree with the first node at the top. Map tasks are disseminated evenly throughout the tree and their results are reduced on the way back up to the ad-hoc master node. This allows the ring to disseminate Map and Reduce tasks without the need for a coordinator responsible for distributing these tasks and keeping track of them, unlike Hadoop.

Their experimental results showed that the latency experienced by a centralized configuration is similar to the latency experienced in a completely distributed framework. However, there are no mechanisms in place to handle churn in the network. If a node joins during a MapReduce job, it will be unable to contribute any of its resources to the problem. If a node in the bounded broadcast tree fails, or worse the ad-hoc master node fails, the data that node is responsible for is lost.

IV. CHORDREDUCE

Marozzo et al. [8] shows that adding additional fault-tolerance features to a MapReduce architecture is worth the added cost of maintenance, as the time lost due to node failures is greatly reduced. However, Marozzo et al. do not explore the benefits of leveraging the properties of a P2P protocol to reduce the complexity of the architecture and completely distribute the responsibility of the task across the network. As a result, P2P-MapReduce still relies on a ratio of masters to slaves to coordinate and organize the network, meaning a percentage of the network is unable to contribute processing power to the actual solving of a problem.

Lee et al. [11] explores the benefits of building a MapReduce module to run on top of Symphony [12], a P2P protocol. Unlike Hadoop, this allows the MapReduce tasks to be executed without the need of a central source of coordination by disturbing tasks over a bounded broadcast tree created at runtime. The Symphony based MapReduce architecture would be greatly improved by the addition of components to handle the failure of nodes during execution. As it stands now, if a node crashes the job will fail due to the loss of data.

While both of these papers have promising results and confirm the capability of our own framework, both solely look at P2P networks for the purpose of routing data and organizing the network, rather than as a means of efficiently distributing responsibility throughout the network and using existing features to add robustness to nodes working on Map and Reduce tasks.

ChordReduce uses Chord to act as a completely distributed topology for MapReduce, negating the need to assign any explicit roles to nodes or have a scheduler or coordinator. ChordReduce does not need to assign specific nodes the task of backing up work; nodes backup their tasks using the same process that would be used for any other data being sent around the ring. Finally, results work their way back to a specified hash address, rather than a specific hash node,

eliminating any single point of failure in the network. These features help prevent a bottleneck from occurring. The result is a simple, distributed, and highly robust architecture for MapReduce.

A. Handling Node Failures in Chord

Due to the potentially volatile nature of a peer-to-peer network, Chord has to be able to handle (or at the very least, tolerate) an arbitrary amount of churn. Section II described how Chord gradually guides nodes into their correct locations after they join the network. The same is true for when a node leaves the network; the stabilize procedure will guide nodes to their correct successors and predecessors. However, we can exert more control over how to handle nodes leaving the network.

When a node n changes his successor, n asks if the successor is holding any data n should be responsible for. The successor looks at all the data n is responsible for and sends it to n . The successor does not have to delete this data. In fact, keeping this data as a backup is beneficial to the network as a whole, as n could decide to leave the network at any point.

Chord specifies two ways a node can leave the ring. A node can either suddenly drop out of existence, or a node can tell the network he is about to leave, letting his successor and predecessor immediately perform the needed changes.

When a node politely quits, he informs both his successor and predecessor and gives them all the information they need to fill the resulting gap. He also sends all of the data he is responsible for to his successor, who becomes responsible for that data when that node leaves. Fingers that pointed to that node would be corrected during the finger maintenance period. This allows for the network to adjust to churn with a minimum of overhead.

It is unlikely that every time a node leaves the network, it will do so politely. If a node suddenly quits, the data it had stored is lost. To prevent data from becoming irretrievable, a node periodically sends backups to its successor. In order to prevent a cascade of backups of backups, the node only passes along what it considers itself responsible for. What a node is responsible for changes as nodes enter and leave the network. If a node's successor leaves, the node sends a backup to his new successor.

Our prototype framework does not implement a polite disconnect; when a node quits, it does so quickly and abruptly. This design ensures that the system would be able to handle churn under the worst of cases. Polite quit could be implemented quite easily.

B. Implementation

ChordReduce is a fully functional Chord implementation in Python. Our installation was designed to be as simple as possible. It consists of downloading our code [13] and running `chord.py`. A user can specify a port and IP of a node in the ring they wish to join. The node will automatically integrate into the ring with this minimal information. The ring as implemented is stable and well organized. We created

Fig. 5: The “dartboard.” The computer throws a dart by choosing a random x and y between 0 and 1. If $x^2 + y^2 < 1^2$, the dart landed inside the circle. A and B are darts that landed inside the circle, while C did not.

problem without the overhead incurring diminishing returns increases. This can be stated as

$$T_n = \frac{T_1}{n} + k \cdot \log_2(n)$$

where $\frac{T_1}{n}$ is the amount of time the job would take when distributed in an ideal universe and $k \cdot \log_2(n)$ is network induced overhead, k being an unknown constant dependent on network latency and available processing power.

Finally, to demonstrate robustness, we need to show that ChordReduce can handle arbitrary node failure in the ring and that such failures minimally impair the overall speed of the network.

A. Setup

To stress test our framework, we ran a Monte-Carlo approximation of π . This process is largely analogous to having a square with the top-right quarter of a circle going through it (Fig. 5), and then throwing darts at random locations. Counting the ratio of darts that land inside the circle to the total number of throws gives us an approximation of $\frac{\pi}{4}$. The more darts thrown, i.e. the more samples that are taken, the more accurate the approximation¹.

We chose this experiment for a number of reasons. The job is extremely easy to distribute. This also made it very easy to test scalability. By doubling the amount of samples, we can double the amount of work each node gets. We could also test the effectiveness of distributing the job among different numbers of workers.

Each Map job is defined by the number of throws the node must make and yields a result containing the total number of throws and the number of throws that landed inside the circular section. Reducing these results is then a matter of adding the respective fields together.

We ran our experiments using Amazon’s Elastic Compute Cloud (EC2) service. Amazon EC2 allows users to purchase an

¹This is not intended to be a particularly good approximation of π . Each additional digit of accuracy requires increasing the number of samples taken by an order of magnitude.

Fig. 6: For a sufficiently large job, it was almost always preferable to distribute it. When the job is too small, such as with the 10^7 data set, our runtime is dominated by the overhead. Our results are what we would expect when overhead grows logarithmically to the number of workers.

arbitrary amount virtual machines by the hour. Each node was an individual EC2 small instance [14] with a preconfigured Ubuntu 12.04 image. These instances were capable enough to provide constant computation, but still weak enough that they would be overwhelmed by traffic on occasions, creating a constant churn effect in the ring.

Once started, nodes retrieve the latest version of the code and run it as a service, automatically joining the network. We can choose any arbitrary node as the stager and tell it to run the MapReduce process. We found that the network was robust enough that we could take a node we wanted to be the stager out of the network, modify its MapReduce test code, have it rejoin the network, and then run the new code without any problems. Since only the stager has to know how to create the Map tasks, the other nodes do not have to be updated and execute the new tasks they are given.

We ran our experiments on groups of 1, 10, 20, 30, and 40 workers, which generated a 10^8 sample set and a 10^9 sample set. Additionally, we gathered data on a 10^7 sample set using 1, 5, 10, 20, 30 workers. To test churn, we ran an experiment where each node had an equal chance of leaving and joining the network and varied the level of churn over multiple runs.

We also utilized a subroutine we wrote called *plot*, which sends a message sequentially around the ring to establish how many members there are. If *plot* failed to return in under a second, the ring was experiencing structural instability.

B. Results

Fig. 6 and Fig. 7 summarize the experimental results of job duration and speedup. Our default series was the 10^8 samples series. On average, it took a single node 431 seconds, or approximately 7 minutes, to generate 10^8 samples. Generating the same number of samples using MapReduce over 10, 20, 30,

Fig. 7: The larger the size of the job, the greater the gains of distributing with ChordReduce. In addition, the larger the job, the more workers can be added before we start seeing diminishing returns. This demonstrates that ChordReduce is scalable.

or 40 nodes was always quicker. The samples were generated fastest when there were 20 workers, with a speedup factor of 4.96, while increasing the number of workers to 30 yielded a speedup of only 4.03. At 30 nodes, the gains of distributing the work were present, but the cost of overhead ($k \cdot \log_2(n)$) had more of an impact. This effect is more pronounced at 40 workers, with a speedup of 2.25.

Since our data showed that approximating π on one node with 10^8 samples took approximately 7 minutes, collecting 10^9 samples on a single node would take 70 minutes at minimum. Fig. 7 shows that the 10^9 set gained greater benefit from being distributed than the 10^8 set, with the speedup factor at 20 workers being 9.07 compared to 4.03. In addition, the gains of distributing work further increased at 30 workers and only began to decay at 40 workers, compared with the 10^8 data set, which began its drop off at 30 workers. This behavior demonstrates that the larger the job being distributed, the greater the gains of distributing the work using ChordReduce.

The 10^7 sample set confirms that the network overhead is logarithmic. At that size, it is not effective to run the job concurrently and we start seeing overhead acting as the dominant factor in runtime. This matches the behavior predicted by our equation, $T_n = \frac{T_1}{n} + k \cdot \log_2(n)$. For a small T_1 , $\frac{T_1}{n}$ approaches 0 as n gets larger, while $k \cdot \log_2(n)$, our overhead, dominates the sample. The samples from our data set fit this behavior, establishing that our overhead increases logarithmically with the number of workers.

Since we have now established that $T_n = \frac{T_1}{n} + k \cdot \log_2(n)$, we can estimate how long a job that takes an arbitrary amount of time to run on a single node would take using ChordReduce. Our data points indicated that the mean value of k was 36.5. Fig. 8 shows that for jobs that would take more than 10^4 seconds for single worker to complete, we can expect there

Fig. 8: The projected runtime using ChordReduce for differently sized jobs. Each curve projects the expected behavior for job that takes a single worker the specified amount of time.

Fig. 9: The projected speedup for different sized jobs.

would still be benefit to adding an additional worker, even when there are already 5000 workers already in the ring. Fig. 9 further emphasizes this. Note that as the jobs become larger, the expected speedup from ChordReduce approaches linear behavior.

Table I shows the experimental results for different rates of churn. The system is relatively insensitive to churn. 40

Churn rate per second	Average Runtime	Speedup vs no churn
0.8%	191.25	2.15
0.4%	329.20	1.25
0.025%	431.86	0.95
0.00775%	445.47	0.92
0.00250%	331.80	1.24
0%	441.57	1.00

TABLE I

nodes in a ChordReduce ring and generated 10^8 samples while experiencing different rates of churn, as specified in Table I. At the 0.8% rate of churn, there is a 0.8% chance each second that any given node will leave the network followed by another node joining the network at a different location. The joining rate and leaving rate being identical is not an unusual assumption to make [8] [15].

Our testing rates for churn are an order of magnitude higher than the rates used in the P2P-MapReduce simulation [8]. Because we were dealing with fewer nodes, we chose these rates to demonstrate that ChordReduce could effectively handle a high level of churn.

Our experiments show that for a given problem, ChordReduce can effectively distribute the problem, yielding a substantial speedup. Furthermore, our results showed that the larger the problem is, the more workers could be added before diminishing returns were incurred. During runtime, we experienced multiple instances where plot would fail to run and the stager would report socket errors, indicating that it had lost connection with a node in the ring. Despite this turbulence, every node managed to reestablish connection with each other and report back all the data. This further demonstrated that we were able to handle the churn in the network.

VI. CONCLUSION AND FUTURE WORK

We presented ChordReduce, a framework for MapReduce that is completely decentralized, scalable, load balancing, and highly tolerant to churn and node failure at any point in the network. We implemented a fully functional version of ChordReduce and performed detailed experiments to test its performance. These experiments confirmed that ChordReduce is robust and effective. ChordReduce is based on Chord, which is traditionally viewed as a P2P framework for distributing and sharing files. Chord provides $\log_2 n$ connectivity throughout network and has built in mechanisms for handling backup, automatically assigning responsibility, routing, and load balancing.

Using Chord as the middleware for ChordReduce establishes its effectiveness for distributed and concurrent computation. The effectiveness of Chord opens up new approaches for tackling other distributed problems, such as supporting databases and machine learning for Big Data, and exascale computations. We intend to further optimize the performance of ChordReduce and extend the middleware to other applications.
